Abstract

underlying the disambiguation effect in word learning.

Young children tend to map novel words to novel objects even in the presence of familiar competitors, a finding that has been dubbed the "disambiguation" effect. Theoretical accounts of this effect have debated whether it is due to initial constraints on children's lexicons (e.g. a principle of mutual exclusivity) or situation-specific pragmatic inferences. We present synthesis of exisiting evidence on this phenomonon through a meta-analysis of the existing literature. We then present two experiments that help distinguish between these theoretical constraints. We conclude by suggesting that multiple cognitive mechanisms may

The role of experience in disambiguation during early word learning

25 Introduction

24

A central property of language is that each word in the lexicon maps to a unique 26 concept, and each concept maps to a unique word (Clark, 1987). Like other important 27 regularities in language (e.g., grammatical categories), children cannot directly observe this general property. Instead, they must learn to use language in a way that is consistent with the generalization on the basis of evidence about only specific word-object pairs. Even very young children behave in a way that is consistent with this one-to-one 31 regularity in language. Evidence for this claim comes from what is known as the 32 "disambiguation" or "mutual exclusivity" (ME) effect (we return to the issue of 33 nomenclaturer below). In a typical demonstration of this effect (Markman & Wachtel, 1988), 34 children are presented with a novel and familiar object (e.g., a whisk and a ball), and are 35 asked to identify the referent of a novel word ("Show me the dax"). Children in this task 36 tend to choose the novel object as the referent, behaving in a way that is consistent with the 37 one-to-one word-concept regularity in language across a wide range of ages and experimental paradigms (Bion, Borovsky, & Fernald, 2012; Golinkoff, Mervis, Hirsh-Pasek, & others, 1994; J. Halberda, 2003; Markman, Wasow, & Hansen, 2003; Mervis, Golinkoff, & Bertrand, 1994). This effect has received much attention in the word learning literature because the 41 ability to identify the meaning of a word in ambiguous contexts is, in essence, the core 42 problem of word learning. That is, given any referential context, the meaning of a word is 43 underdetermined (Quine, 1960), and the challenge for the world learner is to identify the referent of the word within this ambiguous context. Critically, the ability to infer that a novel word maps to a novel object makes the problem much easier to solve. For example, suppose a child hears the novel word "kumquat" while in the produce aisle of the grocery store. There are an infinite number of possible meanings of this word given this referential context, but the child's ability to correctly disambiguate would lead her to rule out all 49 meanings for which she already had a name. With this restricted hypothesis space, the child

is more likely to identify the correct referent than if all objects in the context were considered as possible referents.

Despite – or perhaps due to – the attention that the ME effect has received, there is little consensus regarding the cognitive mechanisms underlying it. Does it stem from a basic inductive bias on children's learning abilities ("bias accounts," see below), a learned regularity about the structure of language ("overhypothesis accounts"), reasoning about the goals of communication in context ("pragmatic accounts"), or perhaps some mixture of these? The goal of the current manuscript is to lay out these possibilities and discuss the state of the evidence. Along the way we present a meta-analysis of the extant empirical literature. We then present two new, relatively large-sample developmental experiments that investigate the dependence of children's ME inferences on vocabulary (Experiment 1) and experience with particular words (Experiment 2). We end by discussing the emergence of ME inferences in a range of computational models of word learning. We conclude that:

- 1. Explanations of ME are not themselves mutually exclusive and likely more than one is at play;
- 2. The balance of responsibility for behavior likely changes developmentally, with basic biases playing a greater role for younger children and learned overhypotheses playing a greater role for older children.
- 3. All existing accounts put too little emphasis on the role of experience and strength of representation; this lack of explicit theory in many cases precludes definitive tests.
 - 4. ME inferences are distinct from learning.

72 A note on terminology.

71

Markman and Wachtel (1988)'s seminal paper coined the term "mutual exclusivity,"
which was meant to label the theoretical proposal that "children constrain word meanings by
assuming at first that words are mutually exclusive – that each object will have one and only
one label." (Markman, 1990, p. 66). That initial paper also adopted a task used by a variety

of previous authors (CHECK THESE CITES, including ???, ???, ???), in which a novel and a familiar object were presented to children in a pair and the child was asked to "show 78 me the x," where x was a novel label. Since then, informal discussions have used the same 79 name for the paradigm and effect (selecting the novel object as the referebnt of the novel word) as well as the theoretical account (an early assumption or bias). This conflation of 81 paradigm/effect with theory is problematic, as other authors who have argued against the 82 theoretical account then are in the awkward position of rejecting the name for the paradigm 83 they have used. Other labels (e.g. "disambiguation" or "referent selection" effect) are not ideal, however, because they are not as specific do not refer as closely to the previous literature. Here we adopt the label "mutual exclusivity" (ME) for the general family of paradigms and associated effects, without prejudgment of the theoretical account of these effects.

ME has also been referred to as "fast mapping." This conflation is confusing at best.

In an early study, S. Carey and Bartlett (1978) presented children with an incidental word

learning scenario by using a novel color term to refer to an object: "You see those two trays

over there. Bring me the *chromium* one. Not the red one, the *chromium* one." Those data

(and subsequent replications, e.g. L. Markson & Bloom, 1997) showed that this exposure was

enough to establish some representation of the link between phonological form and meaning

that endured over an extended period; a subsequent clarification of this theoretical claim

emphasized that these initial meanings are partial (???). Importantly, however,

demonstrations of retention relied on learning in a case where there was a contrastive

presentation of the word with a larger set of contrastive cues (S. Carey & Bartlett, 1978) or

pre-exposure to the object (L. Markson & Bloom, 1997).

Theoretical views of "mutual exclusivity"

What are the cognitive processes underlying this effect? A range of proposals in the literature.

Constraint and bias accounts. Under one proposal, Markman and colleagues 103 (Markman & Wachtel, 1988, Markman et al. (2003)) suggest that children have a constraint 104 on the types of lexicons considered when learning the meaning of a new word – a "mutual 105 exclusivity constraint." With this constraint, children are biased to consider only those 106 lexicons that have a one-to-one mapping between words and objects. Importantly, this 107 constraint can be overcome in cases where it is incorrect (e.g. property names), but it 108 nonetheless serves to restrict the set of lexicons initially entertained when learning the 109 meaning of a novel word. Under this view, then, the disambiguation effect emerges from a 110 general constraint on the structure of lexicons. This constraint is assumed to be innate or 111 early emerging. 112

118

Probabilistic accounts. Regier

115 McMurray

Frank Goodman Tenenbaum

117 Fazly

Over-hypothesis accounts. Lewis & Frank (2013)

Pragmatic accounts. The disambiguation effect is argued to result from online 119 inferences made within the referential context (Clark, 1987, Diesendruck and Markson 120 (2001)). In particular, Clark suggests that the disambiguation effect is due to two pragmatic 121 assumptions held by speakers. The first assumption is that speakers within the same speech 122 community use the same words to refer to the same objects ("Principle of Conventionality"). 123 The second assumption is that different linguistic forms refer to different meanings ("Principle of Contrast"). In the disambiguation task described above, then, children might 125 reason (implicitly) as follows: You used a word I've never heard before. Since, presumably 126 we both call a ball "ball" and if you'd meant the ball you would have said "ball," this new 127 word must refer to the new object. Thus, under this account, the disambiguation effect 128 emerges not from a higher-order constraint on the structure of lexicons, but instead from 129

in-the-moment inferences using general pragmatic principles.

These two proposals have traditionally been viewed as competing explanations of the 131 disambiguation effect. Research in this area has consequently focused on identifying 132 empirical tests that can distinguish between these two theories. For example, Diesendruck 133 and Markson (2001) compare performance on a disambiguation task when children are told a 134 novel fact about an object relative to a novel referential label. They found that children 135 disambiguated in both conditions and argued on grounds of parsimony that the same 136 pragmatic mechanism was likely to be responsible for both inferences. More recent evidence 137 contradicts this view: tests of children with autism, who are known to have impairments in pragmatic reasoning find comparable performance on the disambiguation task between 139 typically developing children and children with autism (de Marchena, Eigsti, Worek, Ono, & Snedeker, 2011; Preissler & Carey, 2005). This result provides some evidence for the view that disambiguation is due to a domain-specific lexical constraint. 142

158

159

Probabilistic representations

Could be the case also that it's a mixture of pragmatic, etc.

We suggest this competing-alternatives approach to the disambiguation effect should 160 be reconsidered. In a disambiguation task, learners may be making use of both general 161 knowledge about how the lexicon is structured as well as information about the pragmatic or 162 inferential structure of the task. Both of these constraints would then support children's 163 inferences. In other words, these two classes of theories may be describing distinct, 164 complimentary mechanisms that each contribute to a single empirical phenomenon with their 165 weights in any given task determined by children's age and language experience, the nature 166 of the pragmatic situation, and other task-specific factors. 167

Search strategy. We conducted a forward search based on citations of Markman and Wachtel (1988) in Google Scholar, and by using the keyword combination "mutual exclusivity" in Google Scholar (September 2013; November 2017). Additional papers were identified through citations and by consulting experts in the field. We then narrowed our

sample to the subset that used one of two paradigms: (a) the canonical experimental 179 paradigm for testing disambiguation behavior (an experimenter says a novel word in the 180 context of a familiar object and a novel object, and the child guesses the intended referent; 181 "Familiar-Novel"), or (b) a paradigm that exposed children to an unambigous mapping of a 182 novel label to a novel object, and then introduced a second novel object and asked children 183 to identify the referent of a second novel label ("Novel-Novel"). For Familiar-Novel 184 conditions, we included conditions that included more than one familiar object 185 (e.g. Familiar-Familar-Novel). From these conditions, we restricted our sample to only those 186 that satisfied the following criteria: (a) participants were children (less than 12 years of 187 age)¹, (b) referents were objects or pictures (not facts or object parts), (c) no incongruent 188 cues (e.g. eye gaze at familiar object). All papers used either forced-choice pointing or 189 eye-tracking methodology. All papers were peer-reviewed with the exception of two dissertations (Williams, 2009; Frank, I., 1999), but all main results reported below remain 191 the same when these papers are excluded [CHECK THIS]. In total, we identified 43 papers that satisfied our selection criteria, and had sufficient information to calculate an effect size. 193

For each paper, we coded separately each relevant condition with each age 194 group entered as a separate condition. For each condition, we coded the paper metadata 195 (citation) as well as several potential moderator variables: mean age of infants, method 196 (pointing or eyetracking), participant population type, estimates of vocabulary size from the 197 Words and Gestures form of the MacArthur-Bates Communicative Development Inventory when available (MCDI; Fenson et al., 1994, Fenson et al. (2007)), referent type (object or picture), and number of alternatives in the forced choice task. We coded participant 200 population as one of three types that have tested in the literature, and have been argued to 201 provide theoretical insight into the underlying mechanisms of the disambiguation effect: (a) 202 typically-developing monolingual children, (b) multilingual children (including both 203

¹This cutoff was arbitrary but allowed us to include conditions from older children in non-typically-developing populations.

bilingual and trilingual children), and (c) non-typically developing children. Non-typically developing conditions included children with selective language imparement, language delays, hearing imparement, autism spectrum disorder, and down-syndrome.

In order to estimate effect size for each conditions, we coded several additional 207 variables: sample size, proportion novel-object selections, baseline (e.g., .5 in a 2-AFC 208 paradigm), and standard deviations for novel object selections, t-statistic, and Cohen's d. 209 For several conditions, there was data were insufficient data reported in the main text to 210 calculate an effect size (no means and standard deviations, t-statistics, or Cohen's ds), but 211 we were able to esimtate the means and standard deviations though measurement of plots (N 212 = 13), imputation from other data within the paper (N = 4; see SI for details), or through 213 contacting authors (N = 26). Our final sample included 157 effect sizes ($N_{\text{typical-developing}}$ = 214 135; N_{multilingual} = 12; N_{non-typically-developing} = 10).

Statistical approach. Effect sizes were computed by a script, compute_es.R,
available in the Github repository. We calculated effect sizes from reported means and
standard deviations where available, otherwise we relied on reported test-statistics (t or d).
All analyses were conducted with the metafor package (Viechtbauer, 2010) using mixed-effect
models with grouping by paper. ² In models with moderators, moderators variables were
included as additive fixed effects.

Results

Bias. We first conducted analyses to determine if there was bias present in the literature. see metalab

 $effect_size_var, random = 1|paper, data = d.$

 $(d_{typically-developing} = 1.19 [0.89, 1.49]; d_{multilingual} = 1.19 [0.89, 1.49]; d_{non-typically-developing} = 1.57 [0.69, 2.44]).$ In the next set of analyses, we ask whether our moderator variables predict variance in these overall effect size estimates.

Trial type, referent type, and number of alternatives. Here we examined the influnce of three methodological varirables – trial type, referent type and number of alternatives – on effect size. Trial type was a significant predictor of effect size, with Familiar-Novel conditions leading to overall larger effect sizes, compared to Novel-Novel conditions ($\beta = -0.71$; Z = -4.65; p = <.001). Referent type (object vs. picture;) and number of alternatives () were not reliable predictors of effect size.

Age. We next examine developmental change in the magnitude of the disambiguation effect. See Table 1.

Experiment 1: ME and Vocabulary

244 Methods

We report how we determined our sample size, all data exclusions (if any), all manipulations, and all measures in the study.

Participants. Children were recruited at the Children's Discovery Museum of San
Jose. Children were asked if they would be willing to play an iPad game with the
experimenter and were informed that they could stop playing at any time. Children first
completed two tasks adapted to iPad; one probing their vocabulary size and one mutual
exclusivity inference task. Included in analyses are 166 children out of a planned sample of
lf0 participants. We ran 62 additional children, who were excluded from analysis based on
planned exclusion criteria of low English language exposure (less than or equal to 75%),

outside the age range of 24-48 month, children who do not give correct answers on > 50% of familiar noun (control) trials, or < 100% of trials completed. Included in our sample were 97 females and 69 males.

Stimuli. Mutual exclusivity inference task was comprised of 19 trials total; three
practice trials of Familiar-Familiar (FF) nouns and 16 experimental trials. Experimental
trials consisted of Novel-Familiar (NF), and Novel-Novel (NN) noun pairings. Of the pictures
presented in the task, 14 objects were familiar and 24 objects were novel. The task included
8 control trials, equally split between NN noun pairings (C-NN) and NF noun pairings
(C-NF) given in random order. Children who did not give correct answers on 50% of control
trials were excluded from the final sample. The remaining 8 trials were divided equally
between NN and NF trials.

The general format of the vocabulary assessment comprised of a 4 image display and a verbal prompt. Two practice trials were administered, followed by 20 experimental trials.

Experimental trials included a fixed set of 20 developmentally appropriate words taken from the Pearson Peabody Vocabulary Test. These words were taken from 9 different domains, including professions, food, outside things, instruments, animals, classroom, shapes, verbs, and household items.

Sessions took place individually in a small testing room away from the 271 museum floor. In the ME inference task, the experimenter introduced them to "Mr. Fox," a 272 cartoon character who wanted to play a guessing game. The experimenter explained that 273 Mr. Fox would tell them the name of the object they had to find, so they had to listen 274 carefully. Children then saw 3 practice trials with two commonly known objects (i.e. cup and cookie). If the participant chose incorrectly for this practice trial, the audio would correct 276 them and allow the participant to choose again. After the practice trials were completed, the task proceeded to run 16 test trials. Reaction times were measured from the onset of the target word. Children could only make one selection. The vocabulary task displayed 4 279 images randomly selected from the fixed bank of 22 images. Participants were prompted to 280

choose one object. Again, reaction times were measured from the onset of the target word and children could only make one selection.

Data analysis. We used R (3.4.1, R Core Team, 2017) for all our analyses.

Results and Discussion

Could be specific strength of particular word in the NF pairing

but we also get it for NN trials alone

Experiment 2: ME and Familiarity

$_{^{288}}$ Methods

283

287

29

We report how we determined our sample size, all data exclusions (if any), all manipulations, and all measures in the study.

		age_group	mean_age	n
91	Participants.	2	30.98684	38
	1	3	40.98571	35
		4	52.16216	37

We planned a total sample of 108 children, 12 per between-subjects labeling condition, and 36 total in each one-year age gorup. Our final sample was 110 children, ages Inf – -Inf months, recruited from the floor of the Boston Children's Museum. Children were randomly assigned to the one-label, two-label, or three label condition, with the total number of children in each age group and condition ranging between 10 and 13.

Materials. Materials were the set of novel objects used in de Marchena et al. (2011),
consisting of unusual household items (e.g., a yellow plastic drain catcher) or other small,
lab-constructed stimuli (e.g., a plastic lid glued to a popsicle stick). Items were distinct in
color and shape.

Procedure. Each child completed four trials. Each trial consisted of a training and a test phase in a "novel-novel" disambiguation task (???). In the training phase, the

experimenter presented the child with a novel object, and explicitly labeled the object with a novel label 1, 2, or 3 times ("Look at the dax"), and contrasted it with a second novel object ("And this one is cool too") to ensure equal familiarity. In the test phase, the child was asked to point to the object referred to by a second novel label ("Can you show me the zot?"). Number of labels used in the training phase was manipulated between subjects.

There were eight different novel words and objects. Object presentation side, object, and word were counterbalanced across children.

Data analysis. We followed the same analytic approach as we registered in 310 Experiment 1, though data were collected chronologically earlier for Experiment 2. 311 Responses were coded as correct if participants selected the novel object at test. A small 312 number of trials were coded as having parent or sibling interference, experimenter error, or a 313 child who recognized the target object, chose both objects, or did not make a choice. These 314 trials were excluded from further analyses; all trials were removed for two children for whom 315 there was parent or sibling interference on every trial. The analysis we report here is 316 consistent with that used in Lewis and Frank (2013), though there are some slight numerical 317 differences due to reclassification of exclusions. 318

err_type	n	pct
changed mind	2	0.0045455
exp err	2	0.0045455
interference	11	0.0250000
no choice	8	0.0181818
recog obj	4	0.0090909

Results and Discussion

319

As predicted, children showed a stronger disambiguation effect as the number of training labels increased, and as noise decreased with age.

	Estimate	Std. Error	z value	$\Pr(> \mathbf{z})$
(Intercept)	0.3076191	0.1046804	2.938650	0.0032965
age_mo_c	0.0464060	0.0112418	4.127972	0.0000366
$times_labeled_c$	0.4832010	0.1287155	3.754022	0.0001740
$age_mo_c:times_labeled_c$	0.0214303	0.0135810	1.577960	0.1145749

We analyzed the results using a logistic mixed model to predict correct responses with age, number of labels, and their interaction as fixed effects, and participant as a random effect. We centered both age and number of labels for interpretability of coefficients. Model results are shown in Table XYZ. There was a significant effect of age such that older children showed a stronger disambiguation bias and a significant effect of number of labels, such that more training labels led to stronger disambiguation, but the interaction between age and number of labels was not significant.

ME in Models of Word Learning

2 Basic statistical biases ("explaining away")

Regier (2005) model shows ME emergent

323

- as noted by Frank, Goodman, Lai, and Tenenbaum (2009), Yu and Ballard (2007)
- model (IBM machine translation model #1, (???) for that; subsequently adapted by
- Nematzadeh, Fazly, and Stevenson (2012)) shows ME as well.
- this is because any conditional probability model will show the same effect
- In other words, Markman and Wachtel (1988)'s sense of a basic inductive bias will
- likely be present in a wide variety of different learning models.
- What is the experience-dependence of ME in these models? In the Frank et al. (2009)
- model, the strength of the ME response scales with the strength of the familiar word's
- mapping; the same thing is true for the other models presumably.
- Open question whether the actual difference in a 2-year-olds' and a 4-year-olds'
- strength of representation of "ball" is what matters here?

Frank et al. (2009) model shows ME, in fact stronger than basic conditional probability. This is in part due to the use of the intention variable.

As a side note, the (???) no retention finding is shown in an even more pragmatic model: Smith, Goodman, and Frank (2013) model shows ME with no retention (though explanation in that model is a little implausible "because the speaker might not be committed to that label and is just using it as a matter of convenience.")

Primary point: No support here for overhypothesis building, which is suggested by 1)
the bilingualism results. In order to fit the bilingual data, in general we'd have to assume
that strength of individual representations in monolinguals and bilinguals was a driver, and
this seems unlikely. 2) no support for E1 vocab findings unless the entire developmental
trend is due to strength of the familiar word representations. In general, the strong — likely
false — claim from all of these models is that the individual representation of the familiar
object strength is the only locus for developmental/population-related change.

McMurray, Horst, and Samuelson (2012) model has ME emerge from the competition dynamics of a neural network.

360

361

362

363

364

365

367

368

369

370

371

Thus, the selection of the novel object is dependent on the learning rule, but not because the network needs to learn something about that object/word. Rather, the weights between the known word/objects and the unused lexical units must decay, and the weights between the novel ones must not in order to create a platform upon which real-time competition dynamics can select the right object. A different type of weight decay (for example, if all weights decayed on each epoch) would not preserve the right form of the weight matrix. However, learning is not the whole story: this pattern of connectivity could not be harnessed in situation time without the gradual settling process represented by the inhibition and feedback dynamics. Moreover, the model's ability to learn from M.E. referent selection may also depend on this competition/feedback cycle. The model must select a single lexical unit and selectively amplify the novel object in order to

380

eventually turn a word-referent link created during M.E. referent selection into a known word by associating the novel object with the novel word over many instances. Thus, while as a real-time process mutual exclusivity is likely to impact learning, it is really more the product of learning than a mechanism of it.

This proposal is complicated but might capture the global and local dynamics in Experiment 1 & 2 better than others.

(???) deal with bilingual data by adding a direct ME-related penalty, not letting it be emergent.

General Discussion

Model	Fixed effect	beta	z-value	p-value
Grand estimate	intrcpt	-0.14 [-0.47, 0.18]	-0.85	0.39
Grand estimate	${\rm ME_trial_typeNN}$	-0.92 [-1.21, -0.62]	-6.13	<.001
Grand estimate	mean_age	$0.04 \ [0.03, \ 0.04]$	11.96	<.001
Typical populations	intrept	-0.08 [-0.43, 0.28]	-0.42	0.68
Typical populations	${\rm ME_trial_typeNN}$	-1.08 [-1.38, -0.78]	-7.05	<.001
Typical populations	mean_age	0.04 [0.04, 0.05]	12.34	<.001
Multilingual populations	intrcpt	-0.07 [-0.62, 0.48]	-0.26	0.79
Multilingual populations	${\rm ME_trial_typeNN}$	$1.64 \ [0.72, \ 2.56]$	3.49	<.001
Multilingual populations	mean_age	0.01 [0, 0.03]	1.57	0.12
Non-typically developing populations	intrcpt	0.66 [-0.57, 1.89]	1.05	0.29
Non-typically developing populations	ME_trial_typeNN	3.06 [0.58, 5.55]	2.42	0.02
Non-typically developing populations	mean_age	$0.01 \ [-0.01, \ 0.03]$	0.77	0.44

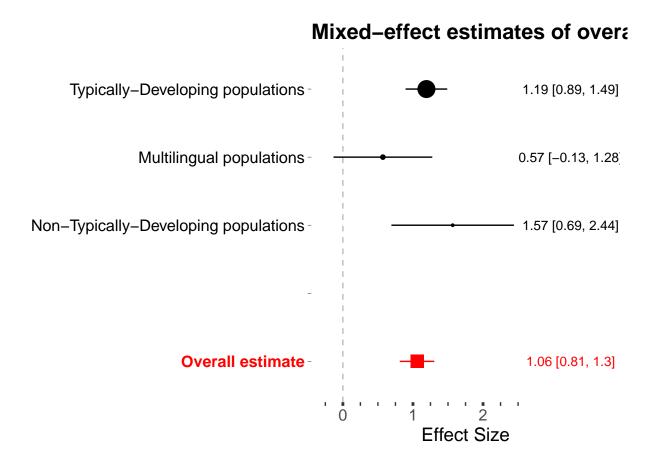

Figure 1. Mixed-effect effect size estimates for all conditions (red) and each of the three sub-populations in our sample. Ranges are 95% confidence intervals. The size of the point for the sub-populations corresponds to sample size.

Disambiguation Development from Meta-Analysis

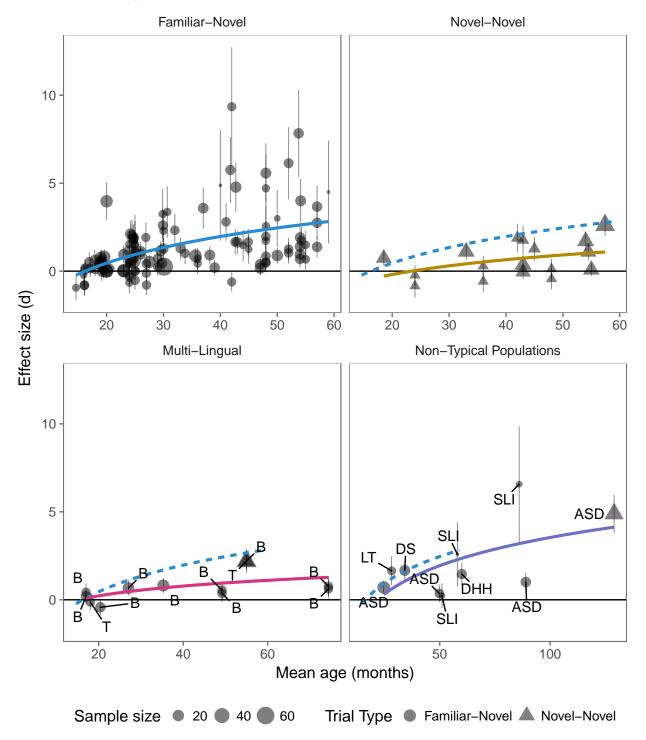

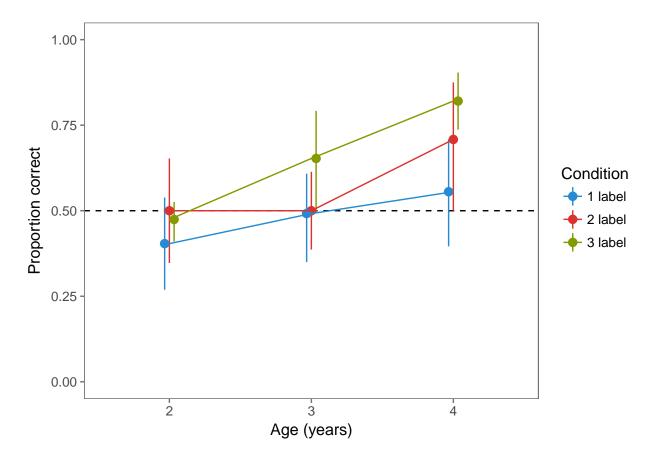

Figure 2. Developmental plots for each moderator. Ranges correspond to 95% confidence intervals. Model fits are log-linear.
